# Passcode Project

Supriya, Wisdom, Yugeen
April 21, 2018

NOTE: We decided to include only 2 graphs in each section (histogram, boxplot, bar graph, ridge density plot, scatter plot) to reduce the length of the report. While doing analysis we looked at all the plots and code for all plots is included in rmd file.

#### 1.Dataset Introduction

The dataset records typing speed of a group of 51 different individuals who have access to the passcode ".tie5Roanl" where each row corresponds to the record of time an individual takes to type the passcode to get access to a system. While an individual has access to the system, no other individual has access to the system. Below is the description of each column in the dataset: The column "X" is row-id ranging from 351 to 20400. The column "subject" contains list of 51 different individuals where each user is assigned with an unique identifier encoded as s002, s003 and so on (note that they are not in sequence from s001 to s051). The column "sessionIndex" is a continuous block of time where an individual has had access to the system.Only one user will be associated with a given session. In our dataset, sessionIndex takes value either 7 or 8 that means we are provided with the information of users participating in session 7 and session 8. The column "rep" is the repetition of the individual passcode entries within a session, which in our dataset ranges from 1 to 50. There are 31 columns that represent the timing information for the passcode. The name of the column encodes the type of timing information. Column names of the form "H.keyname" represents a hold time for the named key, meaning the time from when key was pressed to when it was released. Column names of the form "DD.key1\_name.key2\_name" represents a keydown-keydown time for the named keys meaning the time from when key1 was pressed to when key2 was pressed. Column names "UD.key1" name.key2 name" represents a keyup-keydown time for the named keys meaning the time from when key1 was released to when key2 was

In passcode data analysis we are working with three datasets namely:

1.known.csv: This csv file contains 1776 observations over 35 columns where the individual who entered the passcode is known.

pressed. We observed in our dataset that all column of the type UD.key1\_name.key2\_name, except some, have negative values. And, the times in the column type "DD.key1\_name.key2\_name" is the addition of the times in the two columns "H.keyname" and "UD.key1\_name.key2\_name". For example Consider row 1 observation for user s002: DD.period.t = H.period + UD.period.t 0.3573 = 0.1391 + 0.2182 And this is true for all other observations.

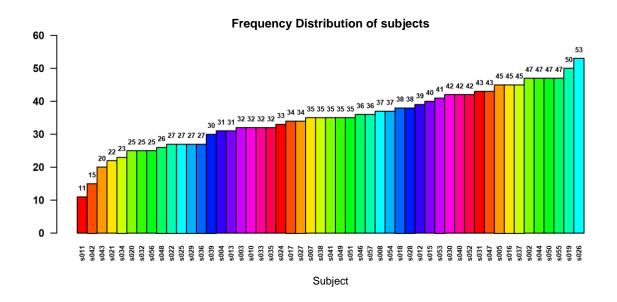

- 2.Unknown.csv: This csv file contains 1795 observations over 33 columns where the individual who entered the passcode is unknown.
- 3.Questioned.csv: This csv file contains 12 sessions where we need to predict the individual who had access to the system.

#### 2.Data Exploration

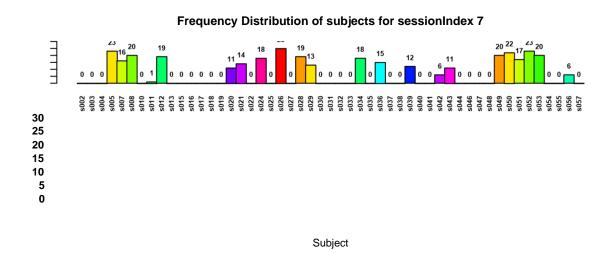

Checking for NA values We checked for missing values and found out that there are no missing values in the dataset.

As mentioned before, there are 51 different individuals recorded in "subject" column who have access to the system, meaning "subject" is a factor variable with 51 levels. The below plot shows the number of observations that belong to each subject and we can notice that the observations are not evenly distributed. The user "s011" logged into system total 9 times which is the least number in our dataset. The user "s026" logged into to system total 43 times

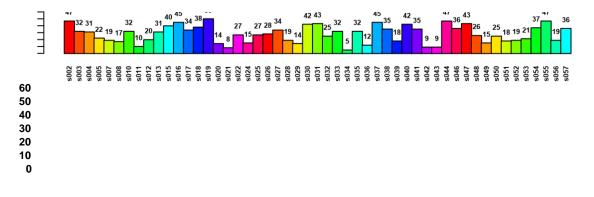

which is the maximum in our dataset. There are other users who have same number of occurrences in our dataset, for eg. users s020, s032, s056 logged into system for total 20 times, user s022, s025, s029, s036 logged into system for total 22 times and so on.

Let us look at the subjects and their occurrences in our dataset grouped by session index. As explained before, session index is the time slot when an individual had access to the system. In our dataset we have two session index values: 7 and 8. There are more occurrences for session index 8 compared to session index 7, to be specific 349 observations for session index 7 and 1427 observations for session index 8. One thing to be noted that session index 8 has occurences of all subject values where as session index 7 does not. The following plots gives a clear idea:

Frequency Distribution of subjects for sessionIndex 8

Subject

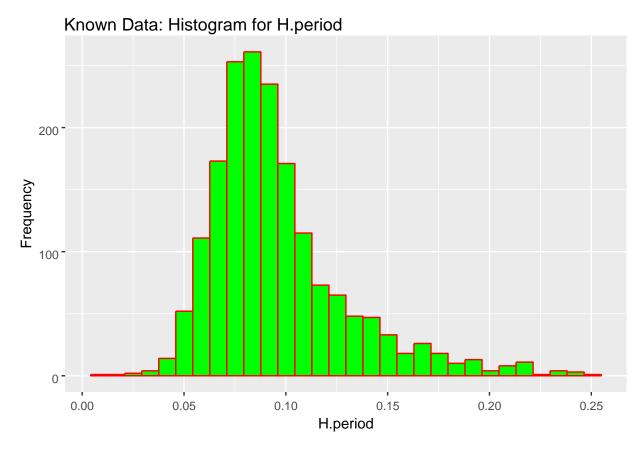

## Looking at independent variables

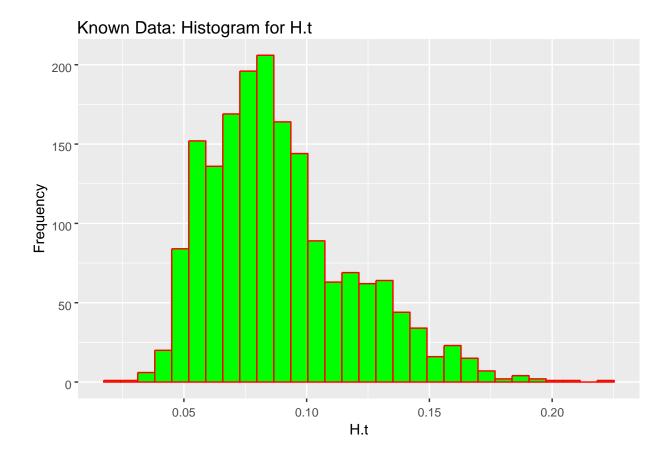

Χ

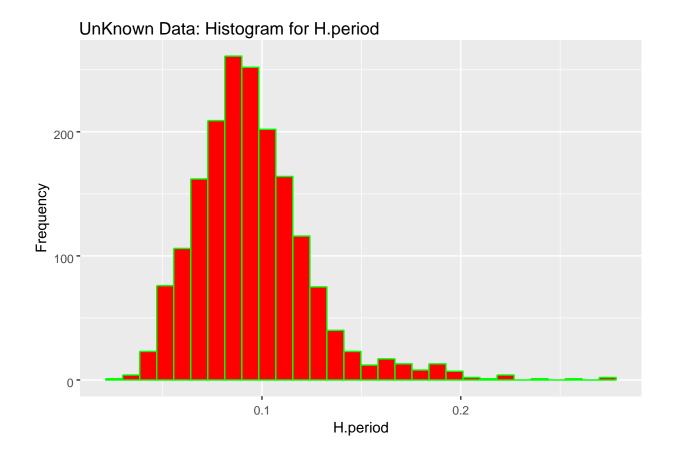

x variable is a row id and hence we removed it from our datset.

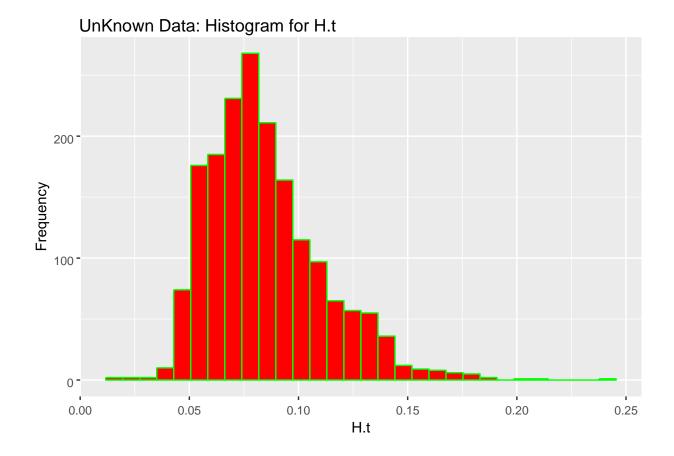

### Histogram for H variables from known and unknown data:

The histogram of the H variables of passcode from known and unknown file has a bell shaped curve meaning their distribution are normal. Few of them are slightly skewed, the reason being most of the values are close to zero and in real world the data follows close to normal distribution.

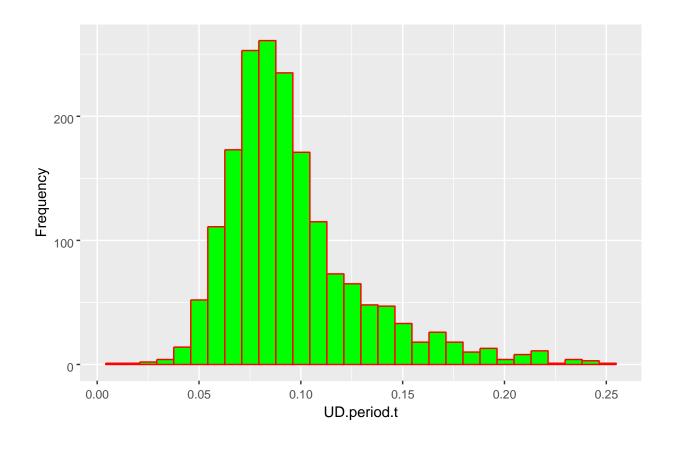

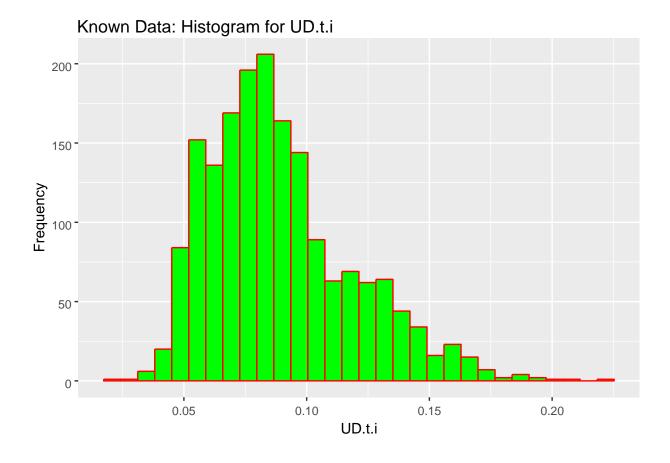

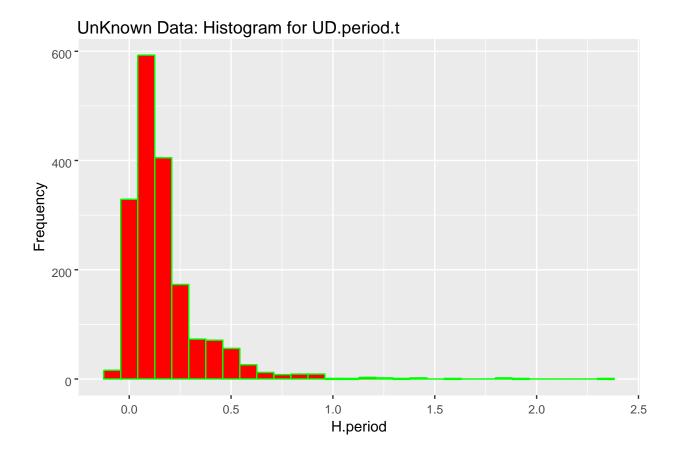

## Histogram for UD variables from known and unknown data:

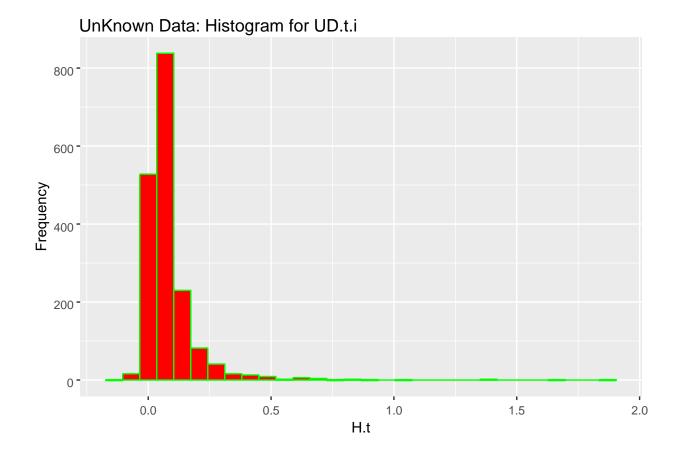

The distribtuion of UD variables from known and unknown file are rightly-skewed. The up-down time of most of the users while typing passcode are takes smaller values.

Known Data: Histogram for UD.period.t

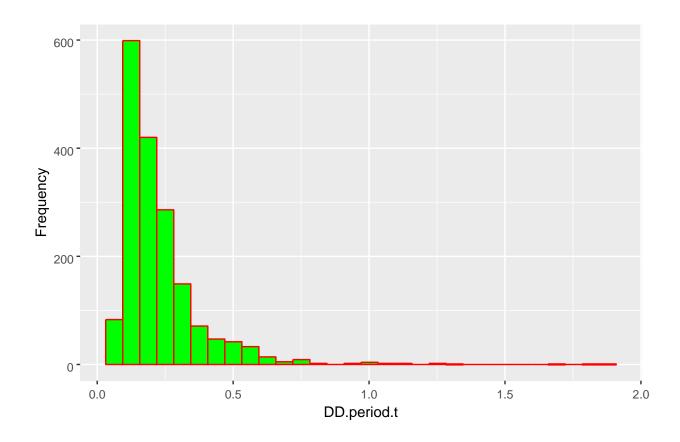

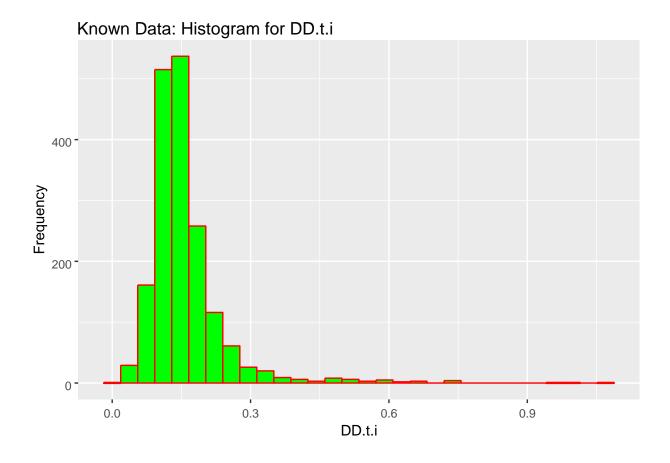

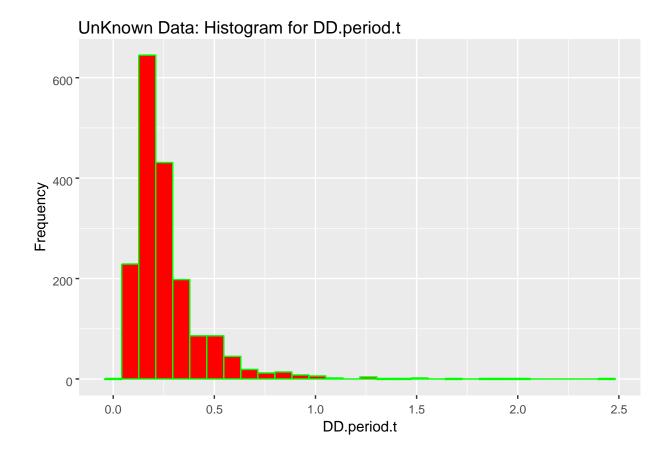

### **Distribution of DD variables:**

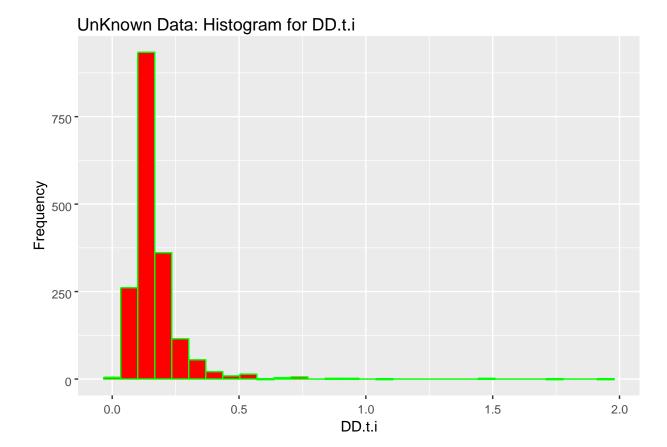

Since DD variables are highly skewed, the information they carry are not different than combined information of H variables and UD variables, hence we decided to not include them in our model.

Known Data: Histogram for DD.period.t

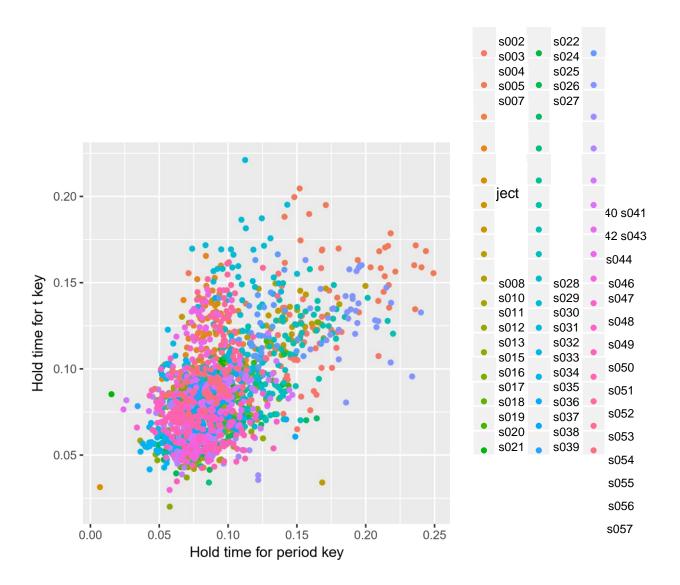

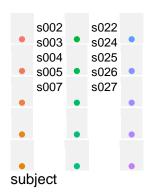

#### rep

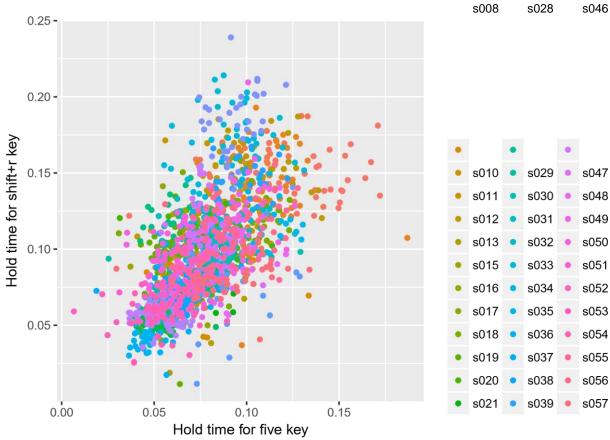

rep is the count of an individual's passcode entries within a session. It takes values from 1 repetition to maximum 50 repetition. There can be different possibilities for a user to enter passcode multiple times in a session: the user types a passcode and leaves the system for some time, the system gets locked if not used for a particular time, so the next time user wants to use the system within same session he needs to enter the passcode again. Other possibility is, user enters wrong passcode and tried multiple times when is a session or the system is designed in a way that it asks user to enter passcode randomly. Since rep variable doesn't carry useful information in predicting user in a session based on typing speed also we are not provided with clear details about rep variable in the document, therefore we decided to not include this variable in our model building process.

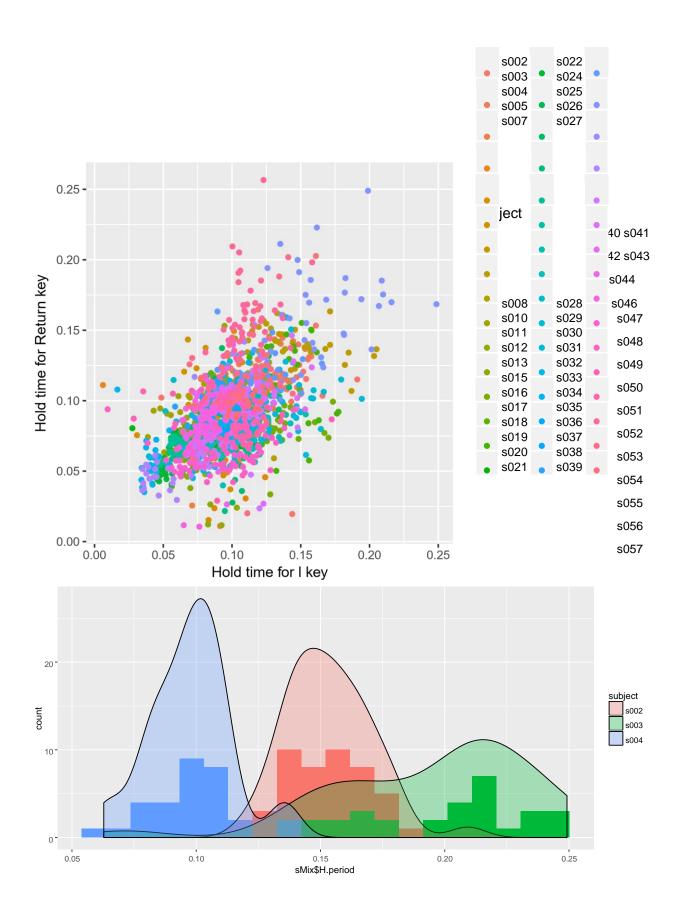

Let us look at the three scatter plots for all users: hold time for period key vs hold time of t key, hold time of five key vs hold time of capital r key and hold time of I key vs hold time of return key. We can see a strong positive linear relationship among the variables and some observations belonging to different classes overlap. The 51 different users are not easily distuniguishable.

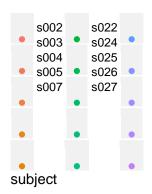

s040 s041 s042 s043 s044

s040 s041

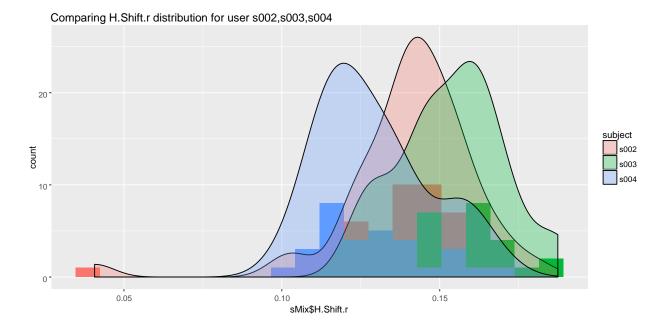

s042 s043

s044

s008 s028 s046

Let us look at the hold time distribution of keys period,t,Shift+r, five, a ,Return for three different users s002, s003, s004. All plots below show gaussian distribution of hold times which is a good indication and we can clearly see some difference in hold time speed of different users. Some graphs show significant difference like hold time for keys period, Shift+r,a and return key.

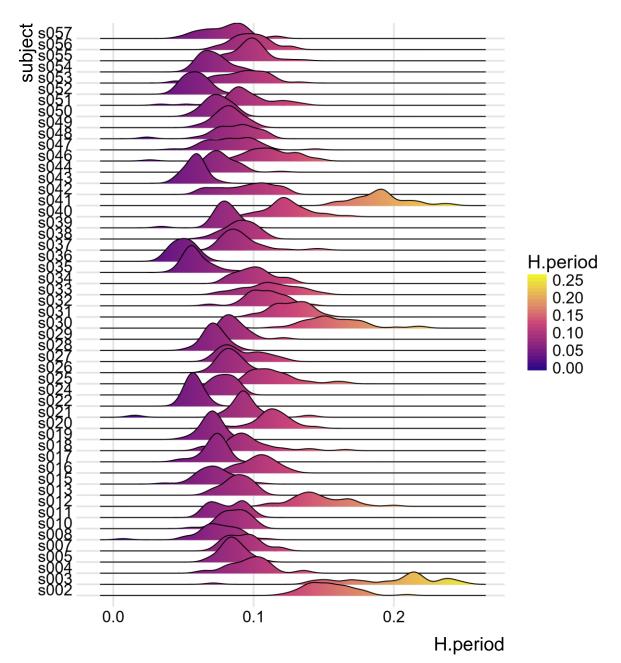

Comparing H.period distribution for user s002,s003,s004

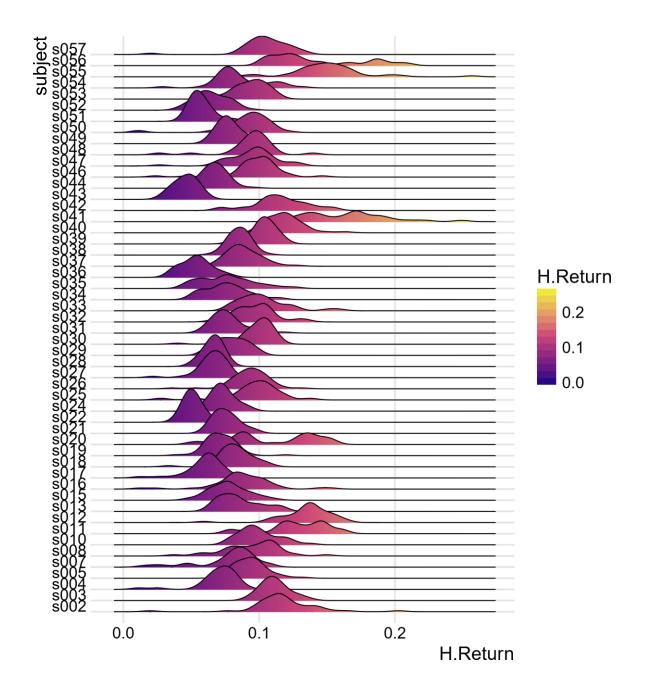

From above graphs we can clearly say that there is difference in typing speed of 3 users. In our dataset we have 51 different users. To look at the difference in distribution of hold times for passcode of all 51 users, we used density ridge plots. We saw in previous scatter plot that for few users timing were overlapping but we are not sure if they have the same timing. From following plots we can clearly see that none of the users have same time distribution and we can say that all 51 users have different time speed for typing passcode.

NOTE: We looked at the distribution plots of all keys in passcode for 51 different users and decided to include only 2 plots in the report. Code for all plots are in rmd file.

Hold time of 51 users for key H.period

Hold time of 51 users for key H.Return

Next we want to see if the sessionIndex makes any difference in the typing speed of 51 different users. We performed t tests of H variables (since they have normal distribution, we assumed equal variance between the two groups, reps in each group are small) to see if the hold time of keys in passcode is different for a user in session 7 and session 8. As explained before, out of 51 users only 22 users have information in both the sessions hence we will look for only these 22 users. Below is the hypothesis testing stated:

Null hypothesis: The true mean of a user in session 7 and session 8 are same.

Alternative hypethesis: The true mean of a user in session 7 and session 8 are different.

```

Two data samples are independent if they come from unrelated populations and the samples does not affect each other. Since most of the p-values are greater than 0.05, we fail to reject the null hypothesis and conclude that sessionIndex 7 and 8 does not make any difference in typing speed of users. Since session 7 and session 8 does not make any difference in typing measurements we decided to not include this variable in our model building.

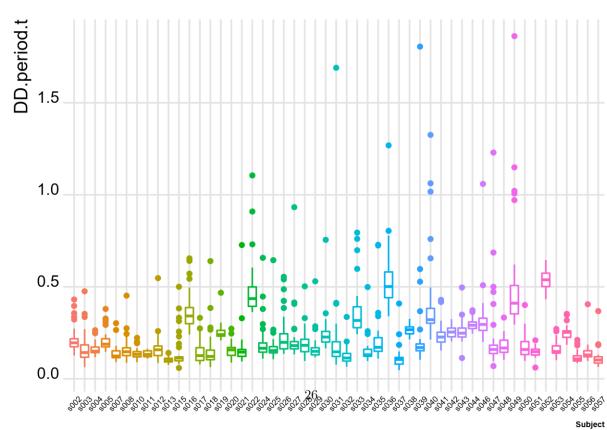

1: Our main goal was to design a good classifier. So, before jumping into directly fitting all the predictors into different classifier methods. We decided to check the correlation between predictors. And, hence the following chart obtained.

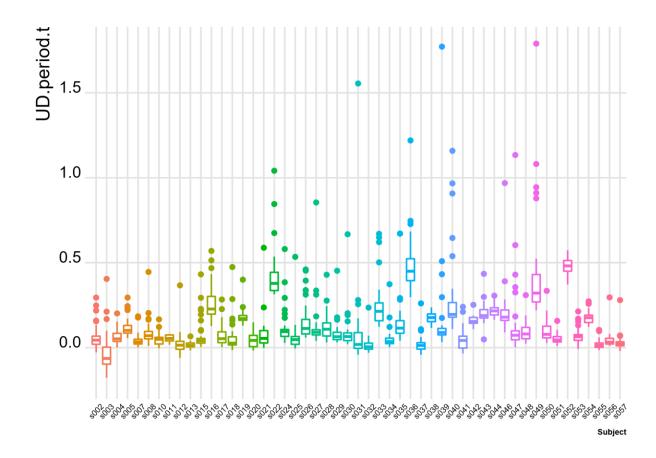

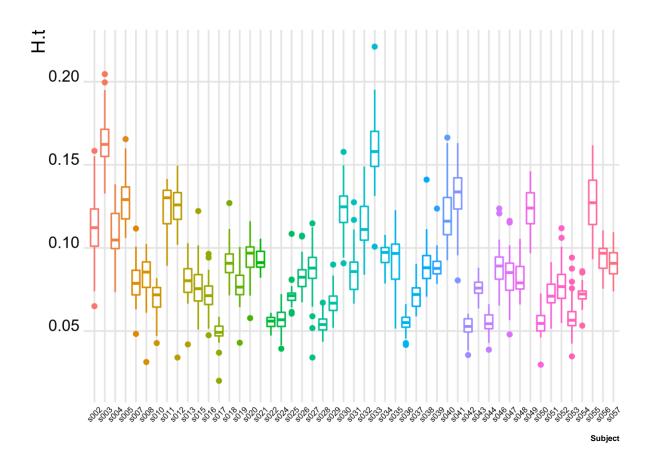

By looking at the above correlation chart, we can easily see that some predictors are highly correlated with each other. For example, the correlation coefficient between **DD.period.t** and **UD.period.t** is 0.98, hence these are highly correlated predictors. In fact, there are other 9 pairs of predictors which are behaving the same nature. Hence, multicolinearity is expected if all the predictors are used to build a classifier.

2: Another method we deployed to obtain importance of predictors is we produced box plots between one predictor versus all the classes on a single plot. And, hence we produced 31 those plots. As to show those 31 boxplots in this report we felt unnecessary, and hence we decided to show following 4 plots.

By looking at the above plots we can clearly see that there is a clear distinction between the most of the users to their typing speeds when they were helding down the password keys **period** and **t**. However, there is not clear distinction between the most of the users on such that the time between pressing down the . key to the time to press down the **t** key, and the time between the . key coming up to the time to press down the **t** key. We obtained the same patterns as mentioned in preceding sentences. Hence, we somehow convienced that those **H** predictors would play the significant roles to build a classifier.

## 3 Obtaining Classifiers

We used createDataPartition method from caret package which creates balanced splits of the data. The random sampling occurs within each class and it preserves the overall class distribution of the data. Below table shows 51 classes and count of observations in each class for original data, train data and split data.

#### i: Multinomial logistics regression

Multinomial logistic regression is a classification method used for multiclass classification problems where the dependent variable is nominal which in our case is subject variable having 51 classes. We are trying to make predictions based on linear combinations of the observed features including all the available variables, only H variables and combination of H and UD variables. We preented Model accuracy and class specific accuracy in our analysis. The multinomial logistics Model accuracy is presented in Table 1 below:

Table 1: Accuracy for GLM Model with H predictors only:

Model	Methods	Accuracy

Model	Methods	Accuracy
Glm using multinom function	Train	0.848987108655617
Glm using multinom function	Test	0.776811594202899
Glm using multinom function	5-fold	0.782113

The model accuracy on test dataset achieved is 77.68116%. We tried 5-fold cross validation approach to look for any improvements in model performance. The model accuracy improved slightly, and it is reported as 78.2113 %. The class S054 have the lowest class specific accuracy of 42.86%, originally it had 14 reps and it predicted only 6. Moreover, we can see most of the class specific accuracy is low. Hence we can conclude that multinomial logistics model performance tends to decrease for the response variable with more than 2 classes. Next we will look how LDA performs, since it is a popular method for multi-class classification problems with more than 2 classes.

#### ii: LDA

Linear Discriminate Analysis (LDA) is a method that uses a linear combination of the observed variables to separate the observations into 2 (or more) classes. A key feature of the LDA is the assumption that the distribution of each individual class type is normal. The method for linear discriminate analysis was conducted using the "Ida" function from the "MASS" library in R. The same basic structure was used for model building and accuracy estimating. The accuracy results are presented in Table 2 below.

#### Test accuracy for LDA model with H predictors only:

**Table 2: Accuracy Table for LDA having only H predictors:** 

Model	Method	Accuracy
LDA having only H predictors	Train	0.818600368324125
LDA having only H predictors	Test	0.815942028985507
LDA having only H predictors	LOOCV	0.810380645177326
LDA having only H predictors	5-fold	0.811373873873874

From Table 2, we observed that the test accuracy (81.6%) performs slightly better than LOOVC (81%) and k-fold (81.1%). With regards to the subject specific accuracy, the model performs well on the subject (s0011) with the lowest rep of 4. The model correctly predicted 3 out of 4 reps (75%) in s0011. This shows that the model is performing well in terms of predicting small reps

#### iii: LDA Model with H and UD predictors

Table 3: Accuracy for LDA having only H and UD predictors:

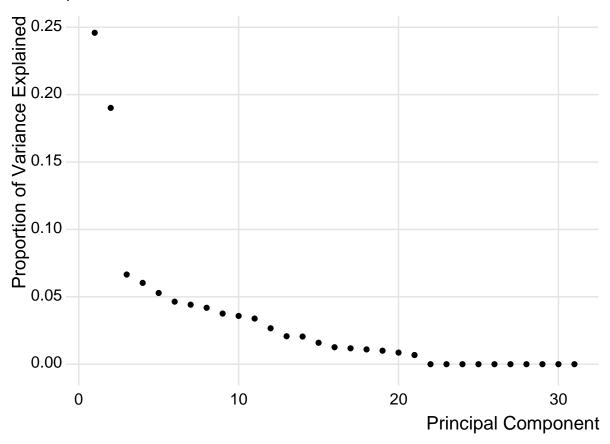

Model	Method	Accuracy
LDA having only H and UD predictors	Train	0.901473296500921
LDA having only H and UD predictors	Test	0.879710144927536
LDA having only H and UD predictors	LOOCV	0.880673834502745
LDA having only H and UD predictors	5-fold	0.873873873873874

Table 3 above displayed the accuracy rate of LDA model with H and UD predictors only. It showed that the LOOCV is performing well in term of overall accuracy (88.1%) as compared to test accuracy and K-fold approach. The subject specific accuracy in Appendix showed that most of the subject specific accuracy are very high with some correctly

predicting all the reps within a subject especially for s010, s017, s022, s024, s025 obtaining 100% subject specific accuracy rate. This shows that the model is performing well.

#### iv: Implementation of PCA on LDA

#### The scree plot for PCA can be obtained as:

By looking at the scree plot we can say that 21 principle componests have explained almost 100% variablity on the data. Hence using 21 principle components for further analysis.

Table 4: Test accuracy for PCA on LDA model

Method	Accuracy
Train	0.906367041198502
Test	0.857344632768362
	Train

V : Bagging and Random Forest using all predictors

#### Vi: Bagging

Bagging involves creating multiple copies of the original training data set using the bootstrap, fitting a separate decision tree on individual copy, and then combining all the trees in order to create a single predictive model. In bagging, each tree is built on a bootstrap data set which is independent of the other trees. Generally, it considers m = p (number of predictors in the model). Implementing a bagging model on the train dataset and assessing the training and testing accuracy, k-fold and loocy yields the output shown in Table 4 below. **Table 5: Accuracy for bagging can be given as:** 

Model	Method	Accuracy
Bagging having all predictors	Train	1
Bagging having all predictors	Test	0.921739130434783
Bagging having all predictors	LOOCV	0.91441441
Bagging having all predictors	5-fold	0.90892065298169

Table 4 displayed the accuracy rate of model with bagging. The k-fold approach appears to be performing well in term of overall accuracy (93.8%) as compared to test accuracy (92.17%) and LOOCV approach (91.44%). The subject specific accuracy in the bagging model seems to be performing better than the LD model, with greater proportion of the subject specific accuracy being 100%. This model performs better than LDA model with H and UD predictors.

#### Vi: Random Forest

Random Forest is an ensemble model that constructs a number of decision trees at training time and output the class that is the mode of the classes output by individual trees. It basically averages the predictions made by tree models to make predictions. Random Forest gives more improved prediction compared to boosting. It considers the important variables first by building randomly different tree models. It considers m = sqrt(p) in the place of mtry for random forests of classification trees, where mtry is number of predictors in the model. Implementing a random forest model on the train dataset and assessing the training and testing accuracy of the model yields the output shown in Table below.

Table 6: Accuracy for Random forest model:

Accuracy	Method	Model
1	Train	Rf having all predictors
0.957971014492754	Test	Rf having all predictors
0.958284229468185	K-fold	Rf having all predictors
0.96171171	LOOCV	Rf having all predictors

In Table 5 above, it can be observed that loocv method records the highest accuracy rate of 96.2% compared to test accuracy (96%). K-fold performed below test and loocv with 78.2% accuracy rate. The subject specific accuracy in the random forest model seems to be performing well with majority of the subjects correctly predicting the reps in each subject.

#### Vii: Boosting

Unlike bagging, in boosting the subset creation is not random and depends upon the performance of the previous models: every new subsets contains the elements that were (likely to be) misclassified by previous models. Hence, in boosting, the trees are grown sequentially: that is each tree is grown using information from previously grown trees. Boosting does not involve bootstrap sampling; instead each tree is fit on a modified version of the original data set.

## [1] 0.9106814

## [1] 0.8231884

Table 7: Test accuracy for boosting model

Model	Method	Accuracy
Bagging having all predictors	Train	0.910681399631676
Bagging having all predictors	Test	0.823188405797101

In Table 6, overall accuracy for test data is 78%, which is quite lower than random forest model and bagging model. The class S054 have the lowest class specific accuracy of 42.86%, originally it had 14 reps and it predicted only 6. Moreover, we can see most of the class specific accuracy is low. Hence we can conclude that multinomial logistics model performance tends to decrease for the response variable with more than 2 classes. Next we will look how LDA performs, since it is a popular method for multi-class classification problems with more than 2 classes.

Viii :SVM Full model

Table 8: Test accuracy for SVM full model

Models	Methods	Accuracy
SVM using linear kernel	Train Accuray	0.98158379373849
SVM using linear kernel	Test Accuracy	0.872463768115942
SVM using poly kernel	Train Accuray	0.982504604051565
SVM using poly kernel	Test Accuracy	0.872463768115942
SVM using radial kernel	Train Accuray	0.996316758747698
SVM using radial kernel	Test Accuracy	0.882608695652174

### Ix: SVM having H and UD:

SVM with kernel value radial performed well compared to SVM kernel values linear and poly. There is not much difference between model accuracy of SVM linear and SVM radial, hence let us look at the class specific accuracy of predicted data using both model.

Table 9: Test accuracy for SVM having H and UD:

Models	Methods	Accuracy
SVM using radial kernel	0.990791896869245	Train
SVM using radial kernel	0.888405797101449	Test set

#### Selection of model:

Base on model performance (accuracy rate), our recommended model is the random forest. This is because the model possesses high overall predictive accuracy (96.2%) and subject specific prediction of individual reps are very high. The subject specific accuracy in the random forest model have majority predicting 100% of the reps in each subject. Also, considering subjects with smaller reps, the model predicted greater proportion for subjects with smaller reps. It can be summarized infollowing points: .Random Forest is intrinsically suited for multiclass problems .Over all model accuracy is good. .Class specific accuracy is good. .Class specific accuracy for classes with fewer reps is good. .We can use huge predictors as they reduces overfitting and is therefore more accurate.
